(Dated: October 22, 2016)

We study the nonlinear E -mode clustering in Lagrangian space by using large scale structure (LSS) N -body simulations and use the displacement field information in Lagrangian space to recover the primordial linear density field. We find that, compared to Eulerian nonlinear density fields, the negative divergence of E -mode displacement fields in Lagrangian space improves the cross-correlation with initial density field by factor of 6 ~ 7, containing 2 orders of magnitude more primordial information. In reality, the displacement field is dominated by linear evolution and insensitive of nonlinear shell-crossing, vorticity or baryonic physics, and thus can be stably solved from only the final matter distributions. This illustrates ability of potential density reconstruction algorithms, to improve the baryonic acoustic oscillation (BAO) measurements from current and future large scale structure surveys.

I. INTRODUCTION

Our universe starts from primordial Gaussian perturbations at a very early stage, and from those fluctuations, the gravitational instability drives the formation of the large scale structure (LSS) distribution of matter [1, 2]. These structures grow linearly until the perturbations are large enough so that the first order perturbation theories are unable to analytically describe the LSS distributions [3]. As a result, the final nonlinear LSS distribution contains higher order statistics, and thus makes it more challenging to be interpreted into basic cosmological parameters. One such example is that, the baryonic acoustic oscillation (BAO) scale can be used as a “standard ruler” to constrain the cosmic expansion history and thus probes the dark energy properties [4], but nonlinear evolution smears the BAO features and lowers the measurement accuracy [5, 6]. There are various attempts to recover earlier stages of LSS, in which statistics are closer to Gaussian [7, 8]. Because Gaussian fields can be adequately described by two-point statistics, ideally after some recovery algorithms, more information can be extracted, more straightforwardly, by power spectra or two-point correlation functions [9, 10].

Standard BAO reconstruction algorithms apply in Eulerian space. They usually smooth the nonlinear density field on linear scale (~ 10 Mpc/ h) and reverse the large scale bulk flows by a negative Zel’dovich linear displacement [11–13]. In the linear Lagrangian perturbation theory (LPT), the negative divergence of the displacement field $-\nabla_q \cdot \Psi(q)$ respect to Lagrangian coordinates q gives the linear density field [14], and in many literatures [15–17] $\nabla_q \cdot \Psi(q)$ is compared with various standard LPT and corrected LPT initial conditions. Their motivation was trying to correct or modify the LPT displacement fields in order that the final positions of particles are brought closer to N -body results. Their results show that all LPT methods are still unable to mimic the shell-crossing scales given by N -body simulation. Because of

the absence of Lagrangian space information in observations, few density reconstruction algorithms are developed according to the relation between displacement and linear density. However, there are techniques to estimate the displacement field from a final distribution of matter. For example, when a homogeneous initial matter distribution is assumed, there is a unique solution of curl-less displacement field to relate the initial and final distributions without shell-crossing. This solution can be solved by a metric transformation equation [18, 19]. In 1-dimensional (1D) case, the exact solution simplifies to an ordering of matter elements by Eulerian coordinates. Zhu *et al.* [20] apply this algorithm to the result of an 1D simulation [3] and obtain an estimated displacement field $\tilde{\Psi}(q)$, and find that this new method well recovers the linear information and reconstructs 1D BAO peak in correlation function. In 3D and more realistic cases, one needs to carefully consider effects of curl, shell-crossing, complicated baryonic physics and biased tracers (galaxies).

Before these steps, we need to quantify the amount of linear information that can be recovered¹ from the full nonlinear displacement field $\Psi(q)$. In $\Psi(q)$ from N -body simulations, (1) shell-crossing effects are fully considered; (2) E -mode displacement field is used for recovering the linear information (although B -mode is also present); (3) the setup is clean in absence of baryons and realistic observables. So it sets the best quality that potential reconstruction algorithms can achieve and further reconstructions by $\tilde{\Psi}(q)$ can be compared with this result. Actually, in the later discussions and our next works we will show that, compared to $\tilde{\Psi}(q)$, additional information (shell-crossing) do not enhance the reconstruction prominently. Further more, we study the scale de-

¹ To avoid ambiguity, we call $\delta_R = -\nabla_q \cdot \Psi(q)$ recovered linear density field, which requires $\Psi(q)$ from N -body simulations, while $-\nabla_q \cdot \tilde{\Psi}(q)$ is called the reconstructed density field.

FIG. 1. Visualization of the nonlinear density field δ_N (top), linear density field δ_L (middle) and the raw recovered density field δ_R (bottom). These projections have 9.375 Mpc/h thickness and 400 Mpc/h per side. The top panel shows the nonlinear displacement field Ψ by the deformed mesh, which traces the LSS of δ_N .

pendent cross-correlation between $-\nabla_q \cdot \Psi(q)$ and linear density field and construct optimal Wiener filters to get the optimal filtered recovered linear density field and recovered linear power spectrum.

In the rest part of the paper, we describe the simulation, density recovery algorithm and Wiener filter setups in section II. We show results in section III. Discussion and conclusion are in section IV.

II. METHOD

We show the LSS simulation and displacement field setups in section II A. In section II B, we recover the linear density field from the displacement field $\Psi(q)$ from simulations. Note that potential reconstruction algorithms are based on an estimated displacement field $\tilde{\Psi}(q)$ instead of $\Psi(q)$. In the following sections we use δ_R to label the recovered linear density field from $\Psi(q)$.

A. Simulation

We use the open source cosmological simulation code CUBE [21]. Cosmological parameters are set as $\Omega_m = 0.27$, $\Omega_\Lambda = 0.73$, $h_0 = 0.68$, $n_s = 0.96$ and $\sigma_8 = 0.83$. Initial conditions are generated at redshift $z = 50$ using Zel'dovich approximation, and using a CLASS transfer function. $N_p = 512^3$ N -body particles are evolved via their mutual gravitational interactions to $z = 0$, in a periodic box with $L = 400$ Mpc/h per side. The code is set to use standard a particle-mesh (PM) algorithm [22] on a two-level mesh grids (details see [23]) and cloud-in-cell (CIC) is used in particle interpolations in force calculation and obtaining the density field $\rho(x)$ in Eulerian coordinates x at late stages. We use density contrast $\delta \equiv \rho/\langle\rho\rangle - 1$ to describe the density fluctuations. The primordial linear density field δ_L is given by the initial stage and

scaled to $z = 0$ by the linear growth factor. In the top and middle panels of Fig.1 we show projections of the nonlinear density field δ_N given by the simulation and the linear density field δ_L . δ_N is obtained by the particle distribution at redshift $z = 0$, and the particles are interpolated by using the cloud-in-cell (CIC) algorithm. Because δ_N is highly nonlinear and follows an approximate log-normal distribution, we plot $\log_{10}(\delta_N + 1)$ instead. The nonlinear evolution of δ_N makes it very different from δ_L in appearance.

The two-point statistics of these density fields are quantified by the cross power spectrum $P_{ij}(k) \equiv (2\pi)^{-3} \langle |\delta_i(k)| |\delta_j(k)| \rangle$, where subscripts i, j may refer to linear (L), nonlinear (N), recovered (R), or noise (n) density fields. When $i = j$ it reduces to the auto power spectrum $P_{ii}(k)$ or $P(k)$. We usually plot the dimensionless power spectrum $\Delta^2(k) \equiv k^3 P(k) / 2\pi^2$.

B. Density Recovery

In the simulation, we use particle-ID (PID) to record the initial (Lagrangian) location \mathbf{q} of particles, and the information is tracked until the $z = 0$ and we can get the Lagrangian displacement vector $\Psi \equiv \mathbf{x} - \mathbf{q}$ for every particle. Then these vectors are interpolated onto the initial Lagrangian coordinates \mathbf{q} of particles and we get the displacement field $\Psi(\mathbf{q})$. To visualize the Ψ field, we draw a 3D uniform mesh over the volume, and use the given Ψ field to deform the mesh according to the direction and physical amplitude of Ψ . In the top panel of Fig.1, The resulting mesh illustrates a pseudo ‘‘curvilinear coordinate’’ similar to [18], however the mesh can be overlapped due to shell-crossing. The densest mesh grids trace the densest structures of δ_N , whereas the undeformed grid positions are the Lagrangian coordinates in which we do the density recovery. The raw recovered density field is given by the differential motion of matter elements,

$$\delta_R = -\nabla \cdot \Psi(\mathbf{q}). \quad (1)$$

Because the recovery processes are implemented on Lagrangian coordinates, δ_R takes the coordinates of \mathbf{q} instead of \mathbf{x} . We just write \mathbf{q} 's Fourier wave number k_q as k to simplify the expression.

To quantify the linear information in the recovered density field, we decompose δ_L in Fourier space as

$$\delta_L(k) = r' \delta_R + \delta_n, \quad (2)$$

where $r' \delta_R$ is completely correlated with linear density δ_L . Correlating equation (2) with δ_R gives

$$P_{LR} = r' P_{RR} + P_{nR}, \quad (3)$$

where $P_{ij} \equiv \langle \delta_i \delta_j \rangle$ denotes the cross power spectrum. Since δ_n is uncorrelated with δ_R , $P_{nR} = 0$. With the definition of cross correlation coefficient $r(\delta_L, \delta_R) \equiv P_{LR} / \sqrt{P_{LL} P_{RR}}$ and bias $b^2 = P_{RR} / P_{LL}$, we solve $r' = P_{LR} / P_{RR} = r b^{-1}$. Note that these computations above and below can also be applied on δ_N for comparison, by replacing ‘‘R’’ with ‘‘N’’ in the equations, while we do not rewrite them explicitly in the paper for simplicity. From these, we plot the cross correlation coefficient $r_{LN} = r(\delta_L, \delta_N)$ and $r_{LR} = r(\delta_L, \delta_R)$ in Fig.2. Clearly, δ_R contains much more linear information on smaller scales.

FIG. 3. Power spectra of δ_L , δ_N , and the decomposition of P_{LL} into correlated parts and noise terms according to equation (4).

According to equation (2), the auto power spectrum is decomposed as

$$P_{LL} = r^2 b^{-2} P_{RR} + P_{nn}, \quad (4)$$

and $P_{nn} = (1 - r^2) P_{LL}$. Then we construct a Wiener filter to filter out the uncorrelated part in δ_R :

$$W(k) = \frac{r^2 b^{-2} P_{RR}}{r^2 b^{-2} P_{RR} + P_{nn}} = r^2. \quad (5)$$

The optimal recovered density is given by

$$\tilde{\delta}_R = W b^{-1} \delta_R, \quad (6)$$

and the optimal recovered power spectrum is given by

$$\tilde{P} = W^2 b^{-2} P_{RR} = W^2 P_{LL} + W^2 b^{-2} P_{NN}. \quad (7)$$

Here W^2 describes the damping of the linear power spectrum.

III. RESULTS

To visualize the above algorithms, a projection of δ_R is plotted in the bottom panel of Fig.1, which looks closer to δ_L compared to δ_N . However the smallest scale structures are unable to be recovered.

As discussed in section II B, Fig.2 shows the cross correlation functions r_{LN} and r_{LR} . The latter extends the correlation with δ_L to smaller scales by nearly an order of magnitude. The extra correlation scales well cover the BAO scales of our interest.

In Fig.3, we show the auto power spectra of δ_L and δ_N in black dashed and blue solid curves. Their difference shows the nonlinear evolution of LSS on small scales. Their cross power (not shown for clarity of the figure) drops to a very low value on

FIG. 4. Probability distribution functions (PDFs) $f(\delta_L, \delta_N)$ and $f(\delta_L, \delta_R)$, showing in the upper and lower panels respectively. Both red curves on x -axes show $f(\delta_L)$, following a Gaussian distribution. The two curves on y -axes in upper and lower panel show respectively $f(\delta_N)$ and $f(\delta_R)$.

scales $k \gtrsim 0.1h/\text{Mpc}$, indicating a loss of linear information in the nonlinear power spectrum P_{NN} . This scenario directly leads to how P_{LL} is decomposed according to equation (4). In nonlinear case (with “ R ” replaced by “ N ” equation (4)), on small scales $k \gtrsim 0.1h/\text{Mpc}$, P_{LL} is dominated by uncorrelated, nonlinear noise, shown in the green dotted line. In the case of δ_R , however, P_{LL} is decomposed into orange dash-dotted correlated part and purple dotted uncorrelated part according to equation (4). The correlated power spectrum is dominated on BAO scales of our interest.

To quantify the improvement of cross-correlation in the power spectrum, we compute the damping factors $W^2(k)$ respectively for the optimal filtered nonlinear and recovered density fields $\tilde{\delta}_N$ and $\tilde{\delta}_R$. We fit Gaussian BAO damping models $\mathcal{D}(k) = \exp(-k^2 \Sigma^2/2)$ to these $W^2(k)$ ’s and give $\Sigma = 1.8 \text{ Mpc}/h$ and $\Sigma = 12 \text{ Mpc}/h$ for $\tilde{\delta}_R$ and $\tilde{\delta}_N$. Since $\mathcal{D}(k) = W^2 = r^4$, we plot $\mathcal{D}_N^{1/4}$ and $\mathcal{D}_R^{1/4}$ over

r_{LN} and r_{LR} in Fig.2. The analyses are repeated with various box sizes (100, 300, 800 Mpc/h per side) and give consistent results.

To further illustrate the improvement in real space one point function correlations, in Fig.4 we use the probability distribution as functions (PDFs) of (δ_L, δ_N) and (δ_L, δ_R) to show the point-point correlation between these two pairs of density fields. Since δ_n in equation (2) is uncorrelated, we use Wiener filtered fields. To keep the consistency over δ_L , δ_N and δ_R , we use the $W(k) = r_{LR}^2$ as the Wiener filter. The grey-scaled plots in the center of both panels show the 2-variable PDFs, whereas their projections onto each variable are just 1-variable PDFs – $f(\delta_L)$, $f(\delta_N)$ and $f(\delta_R)$, shown as red/blue curves on the axes of Fig.4. In the top panel, δ_N shows an approximate log-normal distribution (blue curve) and δ_L follows an expected Gaussian distribution. They show tiny positive correlation in the 2D PDF. Because in Fourier space, δ_L and δ_N have correlations on only very large, linear scales (Fig.2), they result in little correlation in real space – initial density fluctuations in Lagrangian coordinates are evolved/transformed to Eulerian coordinates. As the recovery is done in Lagrangian space, it recovers certain amount of correlation, as shown in the 2D PDF of the bottom panel of Fig.4. One can also see that δ_R follows a much closer Gaussian distribution (blue curve of the bottom panel). In denser regions of δ_L , δ_R is saturated at $\delta_R = 3$, signifying the extreme collapsing of matter [15]: $\delta_R = -\nabla \cdot \Psi = \nabla \cdot \mathbf{q} = 3$. Shell crossing makes δ_R oscillate around 3. These second uncorrelated peaks damp out as we go to higher redshifts. **more?**

IV. DISCUSSION AND CONCLUSION

We extract the actual displacement field of matter elements in cosmological N -body simulations, and use this displacement field to study the LSS nonlinear clustering in Lagrangian space. The displacement information is used to recover the primordial linear perturbations. The result shows a prominent improvement from r_{LN} to r_{LR} in Fig.2 – recovering the lost linear information on nearly an order of magnitude smaller scales. This is achieved by implementing differential movement information of matter elements on Lagrangian coordinates, rather than on Eulerian coordinates. This result illustrates the feasibility of using estimated displacement field $\tilde{\Psi}(\mathbf{q})$ to reconstruct primordial linear density field. A straightforward example of a estimation of $\tilde{\Psi}(\mathbf{q})$ is given by [18, 19]. In reality, one needs to consider all aspects including vorticity, shell-crossing, bias, noise and data complexities. The impact of these factors can be quantitatively compared with the impact of different estimation methods, and with the exact solution by N -body simulations.

The advantage of using displacement field in reconstruction is its insensitive response from highly nonlinearities – densest regions form because matter elements, after shell crossing, stop experiencing the linear extrapolated of Zel’dovich approximation. i.e. the displacement fields are dominated by early stage linear processes, which is the Lagrangian-Eulerian coordinate transform, while late stage shell-crossing, nonlinear and baryonic processes only fine-tunes the final position \mathbf{x} [16]. Compared with estimated displacement fields $\tilde{\Psi}(\mathbf{q})$ by [18], which do not have shell crossing, the additional shell-crossing information in $\Psi(\mathbf{q})$ is uncorrelated with δ_L . This insensitive response from nonlin-

earities enables the stability of reconstruction algorithms, which are expected to give similar results of this paper. In contrast, traditional treatments in reconstruction deals directly on density fields which sensitively relies on nonlinear processes – density values can vary by orders of magnitude due to nonlinear/baryonic physics and many sources of errors.
